Rapid divergence of the copulation proteins in the *Drosophila dunni* group is associated with hybrid post-mating-prezygotic incompatibilities

Abstract

Proteins involved in post-copulatory interactions between males and females are among the fastest evolving genes in many species and this has been attributed to reproductive conflict. Likely as a result, these proteins are frequently involved in cases of post-mating-prezygotic isolation between species. The *Drosophila dunni* subgroup consists of a dozen recently diverged species found across the Caribbean islands with varying levels of hybrid incompatibility. We sought to examine how post-mating-prezygotic factors are involved in isolation among members of this species group. We performed experimental crosses between species in the *dunni* group and find evidence of hybrid inviability. We also find an insemination reaction-like response preventing egg laying and leading to reduced female survival post-mating. To identify that genes may be involved in these incompatibilities, we sequenced and assembled the genomes of four species in the *dunni* subgroup and looked for signals of rapid evolution between species. Despite low levels of divergence, we found evidence of rapid evolution and divergence of some reproductive proteins, specifically the seminal fluid proteins. This suggests post-mating-prezygotic isolation as a barrier for gene flow between even the most closely related species in this group and seminal fluid proteins as a possible culprit.

Introduction

Numerous groups of recently diverged species have been used to study speciation across multicellular taxa (Coyne and Orr 1989; McKinnon and Rundle 2002; Glor *et al.* 2005; Kitano *et al.* 2009; Brekke and Good 2014). These and other studies find an array of complex relationships between species caused by varying levels of divergence across genomes, incomplete isolation and differing forms of reinforcement (Coyne and Orr 2004; Orr 2004; Presgraves 2007; Matute *et al.* 2010; Moyle and Nakazato 2010; Orr *et al.* 2013; Payseur and Rieseberg 2016). Recently diverged species with incomplete reproductive barriers prove to be more useful for understanding how new species can evolve (Coyne and Orr 1989; Gourbière and Mallet 2010; Presgraves 2010). These species groups can be used in QTL studies to identify loci which contribute to the reduced fitness of hybrids (Howard *et al.* 2002; Noor *et al.* 2007; Kitano *et al.* 2009), or to identify genes which may be involved in the early stages of speciation, such as those causing inviability or sterility in the heterogametic sex (a phenomenon known as Haldane's Rule) (Haldane 1922; Coyne and Orr 1989; Orr 1995; Gavrilets and Waxman 2002; Coyne and Orr 2004; Orr 2013).

Several studies have also highlighted that proteins transmitted in the seminal fluid to the female reproductive tract may also drive isolation as a post-mating-prezygotic mating barrier for incompletely separated species, either caused by, or resulting in, reinforcement (Gavrilets and Waxman 2002; Coyne and Orr 2004; Andres *et al.* 2008; Gourbière and Mallet 2010; Larson *et al.* 2012; Larson *et al.* 2013; Ahmed-Braimah 2016; Turissini *et al.* 2017; Matute *et al.* 2020). Barriers to hybridization have

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

34 also been examined in different *Drosophila* species groups, finding varying levels of divergence, and in
35 some cases the mechanisms for isolation between species (PATTERSON 1947; GRANT 1983; COYNE AND
36 ORR 1989; PRESGRAVES 2007; MILLER *et al.* 2010; MATUTE AND AYROLES 2014; AHMED-BRAIMAH
37 2016; TURISSINI *et al.* 2017; MATUTE *et al.* 2020). Some studies, focusing on the effects of heterospecific
38 matings on females, have found drastic changes in the females, including the swelling of the reproductive
39 tract (PATTERSON 1947) and the activation of stress response pathways (AHMED-BRAIMAH *et al.* 2020),
40 likely due to antagonistic interactions between male seminal fluid proteins that the heterospecific female
41 tract (KNOWLES AND MARKOW 2001). These responses likely result in reinforcement of diverging
42 reproductive behavior to prevent such matings (COYNE AND ORR 2004; TURISSINI *et al.* 2017).
43 The *Drosophila dunni* subgroup is found within the *cardini* group in the *Drosophila* subgenus
44 (Supplementary Figure 1) (HEED 1962). This species group diverged across the Caribbean islands
45 thousands of years ago creating endemic populations, each on a different island or set of islands (HEED
46 1962; HOLLOCHER *et al.* 2000; WILDER AND HOLLOCHER 2003). Despite their extended isolation from
47 each other, species are still able to hybridize (to varying levels of success) and are a useful species group
48 for understanding several traits, such as the evolution of pigmentation or reproductive isolation (STALKER
49 AND STREISINGER 1953; PATTERSON 1954; HOLLOCHER *et al.* 2000; WILDER AND HOLLOCHER 2003). In
50 some cases, these hybrid offspring show evidence of Haldane's rule (HALDANE 1922; ORR 2013), with
51 crosses producing only female offspring, or sterile male offspring (HEED 1962).
52 Here we perform experimental crosses in the *dunni* group and find that in some crosses,
53 heterospecific matings reduces female survival compared to conspecific matings, potentially caused by an
54 insemination reaction-like effect (PATTERSON 1947). Using a combination of long-read and short-read
55 sequencing, we assembled the genomes of four species in the *dunni* group to identify proteins driving this
56 incompatibility. We find these genomes are of similar quality and composition as other higher quality
57 genomes in the *Drosophila* subgenus (ZHOU *et al.* 2012; ZHOU AND BACHTROG 2015; GRAMATES *et al.*
58 2017; HILL *et al.* 2019). We also estimate rates of evolution across these genomes and identify several
59 pathways of groups of genes of interest diverging between species (particularly between *D. nigrodunni* and
60 *D. arawakana*), such as a divergence in immune pathways and in seminal fluid proteins.

61 **Materials and Methods**

62 *Drosophila stocks, experimental crosses and survival assays*

63 We obtained stocks for *Drosophila arawakana* (stock number: 15182-2260.00), *D. dunni* (stock number:
64 15182-2291.00), *D. nigrodunni* (stock number: 15182-2311.00) and *D. similis* (stock number: 15182-
65 2321.00) from the Cornell *Drosophila* species stock center. Each species was maintained on standard
66 instant fly food (Formula 4-24, Carolina Biological Supply Company, Burlington, NC) in an incubator at

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

67 23°C. Before experiments, we inbred for three generations. Specifically, we established 10 single fly
68 crosses for each species and chose a single successful cross per generation. We then repeated this for three
69 generations. We then randomly chose one inbred vial to work with for the remainder of the experiments
70 described.

71 *Experimental crosses within and between species*

72 We performed initial crosses in all pairwise combinations of species, for both directions of the cross, as
73 well as within species crosses, to confirm previous assessments of between species viability (HEED 1962;
74 WILDER AND HOLLOCHER 2003).

75 For each species we cleared vials of adults at 9:00AM central time and collected any emerged
76 adults in 3-hour intervals following this, separating by sex. We then used these virgin flies to mate all
77 species in pairwise combinations in 3 replicates. For each replicate we mated 10 males with 10 females (all
78 aged 2-3 days) for 5 days (WILDER AND HOLLOCHER 2003; CENZI DE RÉ *et al.* 2010). We then collecting
79 offspring every day for 30 days following the removal of the parents. After aging virgin F1 offspring for 3
80 days, we separated these into groups of 10 flies of the same parental species and mated with 10 flies of the
81 opposite sex (5 the paternal species, 5 the maternal species) to assess the fertility of the F1 flies. As *D.*
82 *arawakana* appeared to be infected with *Wolbachia*, we sought to cure all species of any bacteria which
83 may affect crosses. We created sublines of each species raised on food containing tetracycline-
84 hydrochloride (0.05mg/ml) for three generations. Following this, we extracted DNA from females of each
85 strain and tested for *Wolbachia* using PCR (wsp-81F (5′-TGGTCCAATAAGTGATGAAGAAAC-3′),
86 wsp-691R (5′-AAAAATTAAACGCTACTCCA-3′), producing a ~600bp product from 10uL reactions,
87 under the following cycling conditions: 94°C for 4 min, followed by 30 cycles of 40 s at 94°C, 40 s at 55°C,
88 1 min at 72°C and a final extension step of 10 min at 72°C) (ZHOU *et al.* 1998). We then repeated
89 experimental crosses, as described above, with the tetracycline cured strains.

90 We assayed female survival for *D. arawakana, D. dunni, D. nigrodunni* and *D. similis* in virgins
91 and following mating, in both uncured and tetracycline cured flies. We considered a cross to be conspecific
92 if we mated within species and a cross to be heterospecific if we mated with the most closely related species
93 where fertile hybrids were found in previous crosses (e.g. *D. dunni* to *D. similis* and *D. arawakana* to *D.*
94 *nigrodunni*). For these crosses we established 5-15 vials of 10 males and 10 females of the given species
95 (with no males when measuring virgin females), all aged 2-3 days. We then recorded the survival of females
96 every day (checking at 10AM Central time) for 30 days, flipping the flies onto new food every 3-4 days
97 and removing males after the first 5 days. We then fit a survival curve across the total data for each cross
98 type using SurvMiner (KASSAMBARA *et al.* 2017) in R (R-CORE-TEAM 2013) and used a Cox's Hazard
99 Ratio to identify significant differences in survival between sets of crosses. For the initial crosses we used
100 the following model:

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

101 $$Survival\ (days\ post\ mating) \sim Female\ species * Male\ species\ (if\ any) + vial$$
102 We set the reference level as the conspecific cross (e.g. *D. arawakana* ♂ *x D. arawakana* ♀) and looked
103 for significant differences from these for interaction terms to determine if unmated females (e.g. *D.*
104 *arawakana* ♀ not mated) or heterospecifically crossed females (e.g. *D. arawakana* ♂ *x D. nigrodunni* ♀)
105 show significant differences from the conspecific cross. To consider the effect of *Wolbachia* infection on
106 these crosses, we repeated these initial crosses alongside the same crosses with *Wolbachia* cured flies (cured
107 as described above) and a Cox's Hazard Ratio was used to determine the effect of *Wolbachia* on survival,
108 and to test for differences in survival between sets of crosses after accounting for *Wolbachia*:
109 $$Survival\ (days\ post\ mating) \sim Female\ species * Male\ species\ (if\ any) + Wolbachia\ infection$$
110 $$+ vial$$

111 *Post-mating dissection of the female reproductive tract*
112 We collected virgin males and females for tetracycline-cured *D. arawakana* and *D. nigrodunni* as described
113 above and aged them 2-3 days. We then established conspecific and heterospecific experimental crosses
114 for 6 replicates of 10 males and 10 females at 10AM central time, as well as virgin control females for 6
115 replicates of 10 females. Following 24 hours of cohabitation, for 3 replicates of each cross, we separated
116 the females for each cross and dissected the reproductive tract. Based on previous work describing the
117 insemination reaction (PATTERSON 1947; GRANT 1983; MARKOW AND ANKNEY 1988), we scored the
118 reproductive tract for each female, identifying if the female had mated (by the presence of sperm), if the
119 reproductive tract appeared to be swollen (relative to the unmated virgin females) or if the reproductive
120 tract was destroyed or damaged (alongside a swollen tract, if possible to tell). We repeated this scoring for
121 the remaining 3 replicates of each cross 24 hours later (48 hours total). We then compared conspecific and
122 heterospecific crosses for rates of mating and rates of insemination reaction occurrence.

123 *Genome sequencing, assembly and annotation*
124 We extracted DNA following the protocol described in (Chakraborty et al. 2017) for *D. arawakana,*
125 *D. dunni, D. nigrodunni* and *D. similis* females. We prepared the *D. dunni* and *D. nigrodunni* DNA as a
126 sequencing library using the Oxford Nanopore Technologies Rapid 48-hour (SQK-RAD002) protocol,
127 which we then sequenced separately using a MinION (Oxford Nanopore Technologies, Oxford, UK) (JAIN
128 *et al.* 2016) (Supplementary Table 1). We also prepared the *D. arawakana, D. dunni, D. nigrodunni* and *D.*
129 *similis* samples as Illumina libraries with a 300bp insert size which we sequenced on an Illumina HiSeq4000
130 to produce 150bp paired-end reads (Supplementary Table 1). We removed Illumina adapters using Sickle
131 (JOSHI AND FASS 2011) and trimmed the Illumina sequences using Scythe (BUFFALO 2018). For the two
132 MinION genomes, bases were called *post hoc* using the built in read_fast5_basecaller.exe program with
133 options: –f FLO-MIN106 –k SQK-RAD002 –r–t 4. For *D. dunni,* raw reads were assembled using

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

134 Minimap2 and Miniasm (parameters: -x ava -o nt -t 8) (LI 2016). We then polished using Racon with Oxford
135 Nanopore Technology reads for three iterations and Pilon with Illumina fragment library reads for three
136 iterations (WALKER *et al.* 2014). For the *D. nigrodunni* genome, we first used wtdbg2 to assemble the
137 genome (parameters: -t 4 -L 1000) (RUAN AND LI 2020). We then created a second assembly using
138 Minimap2. For each, we ran Racon and Pilon for three iterations as described for *D. dunni*, then merged
139 the two *D. nigrodunni* assemblies using Quickmerge (LIU AND YANG 2013). Following this, we polished
140 this merged genome using Pilon for four more iterations. Both assemblies were benchmarked using BUSCO
141 (v 3.0.2) and the *Diptera* database (SIMÃO *et al.* 2015).

142 For *D. similis,* we mapped data to the *D. dunni* genome before Pilon polishing and polished the *D.*
143 *dunni* genome using *D. similis* data in Pilon for three iterations, to insert *D. similis* variants into the genome.
144 Following this we mapped *D. similis* data to this genome using BWA (LI AND DURBIN 2009) and SAMtools
145 (LI *et al.* 2009), and called variants using Picard (BROAD-INSTITUTE 2017) and GATK Haplotypecaller
146 (MCKENNA *et al.* 2010; DEPRISTO *et al.* 2011). We then used BCFtools (NARASIMHAN *et al.* 2016) to filter
147 these variants, removing calls below a quality threshold of 200 and inserted them into the polished genome.
148 This was repeated for two more iterations to create a *D. similis* alternate genome. The same pipeline was
149 followed for *D. arawakana* mapped to the *D. nigrodunni* genome.

150 We used the *D. innubila* transcriptome (HILL *et al.* 2019) as well as protein databases from *D.*
151 *innubila, D. virilis*, *D. melanogaster*, and *M. domestica* in MAKER2 (HOLT AND YANDELL 2011) to
152 annotate each genome, including using *RepeatModeler* (SMIT AND HUBLEY 2008) in an attempt to correctly
153 assign repetitive regions and retraining a HMM using SNAP following each iteration (JOHNSON *et al.*
154 2008). This was repeated for three iterations to generate a GFF file containing gene evidence generated by
155 MAKER2 (HOLT AND YANDELL 2011).

156 Finally, we identified orthologous genomic regions pairwise for each of the four species examined
157 here to each other and to the *D. innubila* genome using progressiveMauve (DARLING *et al.* 2004). We
158 visualized orthologous regions using rCircos (ZHANG *et al.* 2013). We attempted to confirm any apparent
159 structural differences based on progressiveMauve by mapping short reads for each species to a different
160 genome and calling copy number differences using Delly (RAUSCH *et al.* 2012) and dudeML (HILL AND
161 UNCKLESS 2019), taking the consensus of the two tools, but favoring the absence of a copy number variant
162 when we found discrepancies between the two tools.

163 *Assessing the repetitive content across the dunni group*

164 For each genome, we identified the repetitive content *de novo* using RepeatModeler to call the repeats
165 (engine = NCBI) (SMIT AND HUBLEY 2008) and RepeatMasker (-gff –gcalc –s) to identify the repetitive
166 regions (SMIT AND HUBLEY 2013-2015). We also used dnaPipeTE (genome coverage = 1, sample number
167 = 2, cpu = 4, genome size = 168000000) (GOUBERT *et al.* 2015) to identify the repetitive content in the

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

168 short-read data for each species, which we used to make a second map of reference genome repetitive
169 regions using RepeatMasker. For both sets of repeat content assemblies we identified which TE families
170 were shared between species and which were unique to species using blastn (e-value < 10e-5, hsps = 1,
171 alignments = 1). We then identified what proportion of the genome each TE family constituted across
172 species.

173 *Placing the dunni group in the Drosophila phylogeny*

174 To find the consensus species tree despite the differing evolutionary histories of different genes (MENDES
175 AND HAHN 2016), we randomly sampled 100 genes conserved across *Drosophila* and humans from and
176 extracted these from our four focal species, as well as from several other *Drosophila* species, taken from
177 Flybase (GRAMATES *et al.* 2017) and the NCBI genomes database (ZHOU *et al.* 2012; HAMILTON *et al.*
178 2014; PALMIERI *et al.* 2014; ZHOU AND BACHTROG 2015; KITTS *et al.* 2016; HILL *et al.* 2019). We then
179 aligned each gene group separately using MAFFT (--auto) (KATOH *et al.* 2002) and created a multiple gene
180 super-tree based on the consensus of each gene tree, following 100 bootstraps with PhyML (-b 100 -N 100
181 -GTR -gamma 8) (LE AND GASCUEL 2008; GUINDON *et al.* 2010). We also generated gene trees for each
182 of the 100 genes independently, following the same protocol. In this case 66 of the 100 trees gave the same
183 topology of the *dunni* group as the total tree, while 7 trees had distinct topologies and 27 trees gave the
184 topology of *D.similis* as an outgroup to the other three species, with *D. dunni* a sister to the *D. nigrodunni-*
185 *D.arawakana* complex.

186 *Estimating rates of evolution across the dunni group*

187 For each gene in the genomes of our four focal species, we identified orthology to each other and to genes
188 in *D. innubila* using blastp (e-value < 0.00001, hsp = 1 alignment = 1) (ALTSCHUL *et al.* 1990). For each
189 set of orthologs, we aligned using PRANK to generate a codon alignment and gene-tree (LÖYTYNOJA
190 2014), as subtle differences between the species tree and gene trees can result in false estimates of
191 divergence (MENDES AND HAHN 2016). We then estimated rates of both non-synonymous and synonymous
192 substitutions using codeML (YANG 2007), we estimated specific rates of evolution along each branch of
193 the *dunni* group and leading into the *dunni* group using *D. innubila* as an outgroup (model 0) (YANG 2007).
194 Specifically, we estimated synonymous divergence (dS), non-synonymous divergence (dN) and the
195 proportion of the two values (dN/dS). Finally, we also estimated rates of evolution across the entire *dunni*
196 group phylogeny using codeML (models 7 & 8) (YANG 2007), choosing the best fitting model using a
197 likelihood ratio test (*p*-value < 0.05).

198 Using the estimated rates of evolution, we then compared the rates of evolution across the entire
199 phylogeny and on specific branches to each species, for genes of similar levels of synonymous divergence
200 (dS, windows of 0.001 dS, e.g. all genes within 0.001 dS of each other) we found the 97.5th upper percentile

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

201 for dN/dS. For the closely related species pairs (*D. nigrodunni* and *D. arawakana*, *D. dunni* and *D. similis*)
202 we compared measures of dN/dS between species and found the 97.5th upper percentile for dN/dS per
203 species per window of dN/dS for the paired species (0.001, sliding 0.001).
204 We then took outlier genes (e.g. genes above the 97.5th percentile in each category) and looked for
205 enrichments in gene ontology categories compared to non-outlier genes using GOrilla (EDEN *et al.* 2009).
206 For GO categories of interest, such as those enriched for duplications or for high levels of dN/dS, we
207 compared dN/dS of genes in these categories to the nearby genomic background. For each gene we
208 extracted nearby genes (within 100kbp up or downstream on the same chromosome), of similar divergence
209 levels on each branch (within 0.01 dS), we then found the difference in dN/dS between the median of the
210 background genes and the focal gene. We then used a Wilcoxon-Rank Sum test to identify GO categories
211 on each branch with significantly higher (or lower) dN/dS than the background.
212 Using the annotations of all species and *D. innubila,* we identified genes with more than one copy
213 in one species, relative to all other species. We confirmed this by estimating copy numbers of genes in each
214 species using short read information and dudeML (following the tutorial pipeline for N = 1) with the short
215 read information mapped to the genome of the sister species (HILL AND UNCKLESS 2019). We then used
216 GOrilla (EDEN *et al.* 2009) to identify Gene ontology categories that are enriched for duplicates on specific
217 branches, which we confirmed using PANTHER (THOMAS *et al.* 2003).

218 *Statistics*

219 We used R for all statistics in this analysis (R-CORE-TEAM 2013), and ggplot2 for data visualization and
220 figure production (WICKHAM 2009).

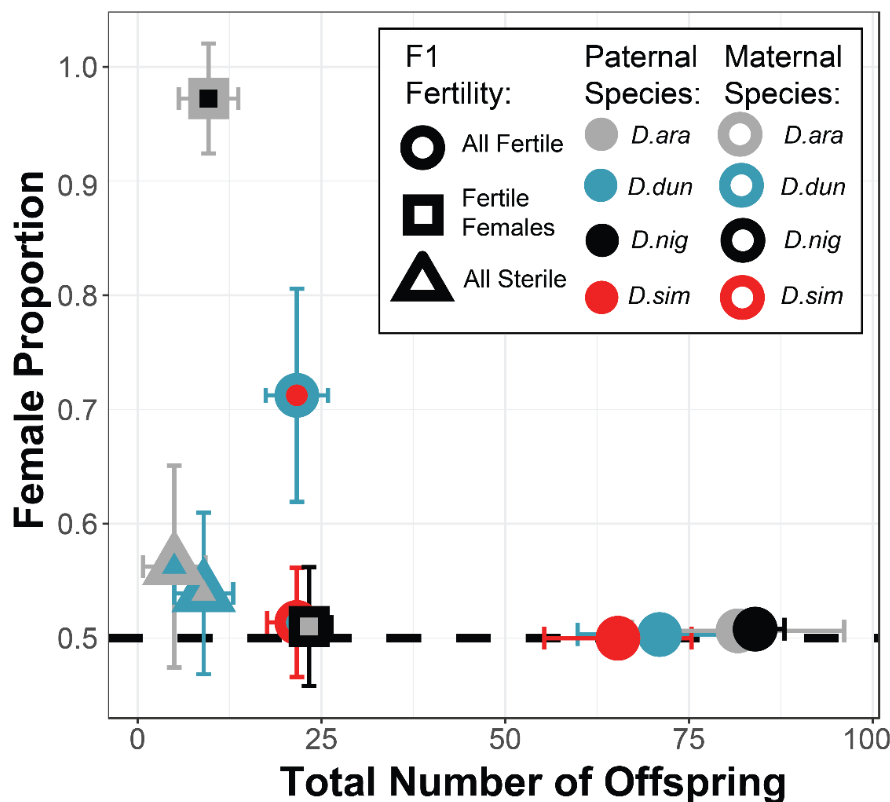
221 **Results**

222 *The Drosophila dunni group shows varying levels of hybrid compatibility*

223 The *Drosophila dunni* group is a species group endemic to islands in the Caribbean, with each island
224 inhabited by a different complement of species (STALKER AND STREISINGER 1953; WILDER AND
225 HOLLOCHER 2003; CENZI DE RÉ *et al.* 2010). These species have varying levels of hybrid incompatibilities,
226 with some crosses producing viable offspring (e.g. *D. dunni* x *D. similis*) and others producing sterile
227 offspring (e.g. *D. arawakhana* x *D. dunni*) or no offspring (e.g. *D. nigrodunni* x *D. similis*). In keeping with
228 Haldane's rule (HALDANE 1922), some produce sterile males, or no males at all (Figure 1, Supplementary
229 Table 2, e.g. *D. nigrodunni* x *D. arawakhana*). Despite divergence on levels comparable to the *D.*
230 *melanogaster* subgroup (Supplementary Figure 1, Supplementary Table 3), there are no characterized
231 inversions between species (STALKER AND STREISINGER 1953; CORDEIRO *et al.* 2014), allowing
232 differences across the species group to be investigated with a higher resolution than the *D. melanogaster*
233 group allows.

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

234 **Figure 1:** Mean number of offspring produced by three replicates of 10 females of each species when
235 crossed to males of different species. Points of the same color represent conspecific crosses while dots with
236 a different center represent a cross between two different species. Point shape shows the state of fertility of
237 F1 offspring, either both fertile, both sterile or only females fertile. Error bars show the standard deviation
238 of offspring count and sex ratio across replicates. *D. ara* = *D. arawakana, D. dun* = *D. dunni, D. nig* = *D.*
239 *nigrodunni, D. sim* = *D. similis*. While all we performed all pairwise heterospecific crosses, only crosses
240 which produced offspring are shown on the plot.



241

242 Given the variety in levels of divergence and isolation between species, we examined the differences in this
243 species group and identify patterns of divergence between species that could be associated with the
244 reproductive isolation. Our focus is on the two hybrid crosses which produce some compatible offspring,
245 such as with *D. nigrodunni* and *D. arawakana*, in which one direction of the heterospecific cross produces
246 only female offspring (Figure 1).

247 *Drosophila arawakana males reduce the lifespan of D. nigrodunni females*

248 We next determined if there was evidence of further effects, beyond offspring viability (precopulatory,
249 prezygotic and postzygotic) on hybridization. To do this, we established crosses between species, focusing
250 on crosses that produced some fertile offspring (*D. nigrodunni* ♀ x *D. arawakana* ♂, *D. arawakana* ♀ x *D.*
251 *nigrodunni* ♂, *D. similis* ♀ x *D. dunni* ♂, *D. dunni* ♀ x *D. similis* ♂, Supplementary Table 2). We also

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

252 established matched crosses within species, and a matched control of virgin females. For each cross we
253 recorded the survival of females following 5 days of mating.

254 In all cases, and consistent with studies in *D. melanogaster* (CHAPMAN et al. 1993; WIGBY AND
255 CHAPMAN 2005), virgins generally survive longer than mated females, though not significantly in some
256 cases (Figure 2, Cox Hazard Ratio z-value = 3.868, *p*-value = 0.00011). The heterospecific crosses showed
257 no difference from the conspecific crosses for *D. similis* and *D. dunni* (Figure 2, Cox Hazard Ratio z-value
258 = -0.488, *p*-value = 0.62545), though *D. similis* heterospecifically mated females lived longer than
259 conspecifically mated females (Figure 2, Cox Hazard Ratio z-value = 2.153, *p*-value = 0.03134). In contrast,
260 when *D. nigrodunni* females are crossed to *D. arawakana* males, females have significantly decreased
261 survival compared to conspecific crosses and virgin females (Figure 2, Cox Hazard Ratio z-value = -3.360,
262 *p*-value = 0.00078), the same cross which also produced only female offspring (Figure 1).

263 **Figure 2: Survival of females postmating.** Survivial probability of females for each species used in each
264 cross, compared to virgin female survival. Females are separated by species, and grouped as virgins,
265 conspecific crossed (crossed to own species), heterospecific crossed (crossed to a different species). In the
266 case of heterospecific crosses, *D. arawakana* is only crossed to *D. nigrodunni* and *D. dunni* is only crossed
267 to *D. similis*.

268 
bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

269 As the *D. arawakana* strain examined was infected with *Wolbachia* and the *D. nigrodunni* was not,
270 we cured all strains of bacteria using tetracycline-hydrochloride and repeated the survival assays. All
271 females in this second block have reduced survival compared to the original survival assay, (Supplementary
272 Figure 2, Cox Hazard Ratio z-value = -5.654, *p*-value = 1.56e-08), suggesting a difference in the two
273 experiments that could be attributed to Tetracycline-Hydrochloride exposure. In the tetracycline exposed
274 flies, we again find reduced survival in the *D. nigrodunni* ♀ *x D. arawakana* ♂ cross compared to the
275 conspecific crosses (Supplementary Figure 3, Cox Hazard Ratio z-value = -3.815, *p*-value = 0.000136).

276 *The insemination reaction may be associated with the reduced female survival and reduced number of*
277 *hybrid offspring*

278 In several other hybrid crosses between species in the *Drosophila* subgenus of *Drosophila*, other studies
279 have highlighted a reaction between the seminal fluid of one species with the environment of the
280 reproductive tract in the other species, called the insemination reaction (PATTERSON 1947; GRANT 1983;
281 MARKOW AND ANKNEY 1988). In the hours following mating, the reproductive tract swells, and, in some
282 cases, proteins in the seminal fluid cause the formation of a "reaction mass", a large dark mass which can
283 burst through the wall of the tract (PATTERSON 1947).

284 Given the reduced survival of *D. nigrodunni* females following mating with *D. arawakana* males
285 and the reduced number of hybrid offspring, we hypothesized that an incompatibility between the diverged
286 seminal fluid proteins and the heterospecific reproductive tract could cause an abnormally deleterious
287 reaction mass which reduces female survival.

288 We established experimental crosses within and between *D. arawakana* and *D. nigrodunni*. Then,
289 24 and 48 hours after crossing we dissected the females to identify whether sperm was present in the female
290 reproductive tract (Figure 3A and B), and score for abnormal reproductive tracts consistent with the
291 insemination reaction (Figure 3C and D). Interestingly, there was no significant differences between the
292 number of mated females 24 and 48 hours after establishing crosses (Logistic regression: sperm presence
293 ~ collection date: z-value = 1.285, *p*-value = 0.198873), but did score significantly fewer mated females in
294 heterospecific crosses versus conspecific crosses (Logistic regression: sperm presence ~ cross type: z-value
295 = -2.948, *p*-value = 0.00319). In several mated females when compared to virgin females, we find a swelling
296 of the reproductive tract consistent with the insemination reaction (Figure 3C). Exclusively in several
297 heterospecifically crossed females, we also saw damaged and destroyed reproductive tracts (Figure 3D).
298 We find a significant excess of swollen/damaged tracts in heterospecifically mated *D. nigrodunni* compared
299 to conspecific controls (Figure 3E, Logistic regression: swollen tract ~ *D. nigrodunni* cross type: z-value =
300 4.723, *p*-value = 2.32e-06). While we do find swollen tracts in *D. arawakana* females we find no difference
301 between heterospecific and conspecific females (Figure 3E, Logistic regression: swollen tract ~ *D.*
302 *arawakana* cross type: z-value = 0.493, *p*-value = 0.622162).

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

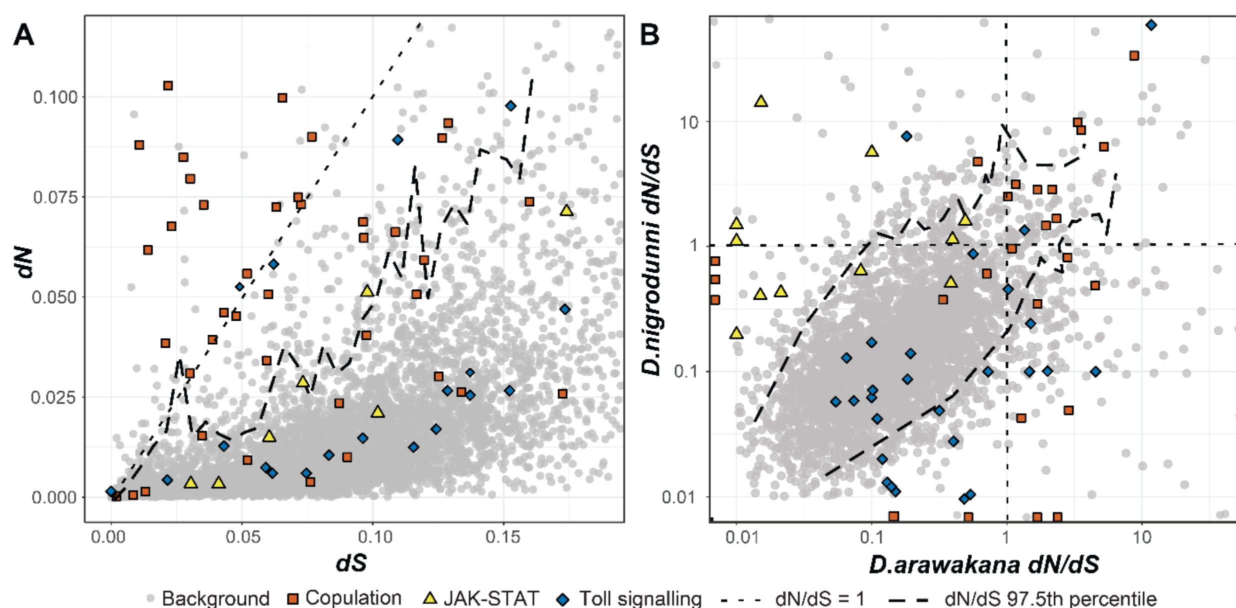
313 *Genes involved in copulation and immune defense have high rates of divergence between species*
314 We reasoned that these incompatibilities between species could be caused by a divergence in copulation
315 proteins. Previous work has suggested that females may be susceptible to bad reactions following hybrid
316 matings due to no protection from the other species accessory gland proteins (MARKOW AND ANKNEY
317 1988; KNOWLES AND MARKOW 2001). Specifically, that there is an arms race between sexes to
318 block/unblock the female reproductive tract and that females of other species have not evolved to suppress
319 these reactions. Based on this, we sought to examine the levels of divergence and identify rapidly evolving
320 genes between species. We sequenced, assembled and annotated the genomes of each species involved (see
321 Materials and Methods), producing two high quality genomes with high synteny to each other and to *D.*
322 *innubila* (Supplementary Tables 1 & 4 and Supplementary Figure 4A), and two assemblies derived from
323 these *de novo* assemblies. The two *de novo* assemblies had high BUSCO scores (*D. dunni* scored 93.9%:
324 2627 complete, 79 fragmented and 93 missing out of 2799 total; *D. nigrodunni* scored 97.3%: 2721
325 complete, 37 fragmented and 41 missing out of 2799 total). Consistent with previous findings we find no
326 large structural rearrangements between genomes, and no evidence of fixed inversions between species in
327 the *dunni* group (HEED 1962; CORDEIRO *et al.* 2014), though we do find several inversions between the
328 next closest whole genome available, *D. innubila* on Muller elements B, C and D (*D. nigrodunni* shown in
329 Supplementary Figure 4B). We annotated the *dunni* group genomes using a transcriptome from *D. innubila*
330 in MAKER (HOLT AND YANDELL 2011) and found between 10752 and 11581 genes in each species, most
331 of which show orthology to previously identified genes in *D. virilis, D. melanogaster* or *D. innubila*
332 (Supplementary Table 5) (HILL *et al.* 2019).
333 When examining the repetitive content of each species, we see an expansion of Helitrons and LTRs
334 along the *D. dunni/D. similis* branch, resulting in higher TE content in these two species compared to *D.*
335 *nigrodunni/D. arawakana* (Supplementary Figure 5). We also find species-specific expansions of satellites,
336 particularly in *D. arawakana* and *D. nigrodunni,* where ~4% of the genome appears to be satellite sequences
337 exclusive to that species (Supplementary Figure 5).
338 We identified orthologous genes across species using BLAST (ALTSCHUL *et al.* 1990) with *D.*
339 *innubila* as an outgroup when possible. For each group of orthologous genes, we identified the proportion
340 of synonymous (dS) substitutions and amino acid changing, nonsynonymous substitutions (dN) (per
341 possible synonymous or nonsynonymous substitution, respectively) occurring on each branch of the
342 phylogeny using codeML (branch-based approach, model 0) (YANG 2007). We also estimated these
343 substitution rates across the entire *dunni* group phylogeny (sites-based approach, model 7 & 8) (YANG
344 2007). This allowed us to calculate dN/dS to identify genes showing signatures of rapid or unconstrainted
345 evolution on any branch of the phylogeny, or across the entire tree. For the dN/dS estimates on each branch,
346 we identified genes in the upper 97.5th percentile for dN/dS in windows of 0.01 dS. dN/dS in *D. nigrodunni*

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

347 is significantly correlated with dN/dS in *D. arawakana* (Figure 2B), as well as in all other pairwise species
348 comparisons (Supplementary Table 6, Pearson's correlation coefficient = 0.844, t = 7.3774, df = 7569, *p*-
349 value = 1.786e-13), and that similar proteins are rapidly evolving across the entire group. Copulation
350 proteins (specifically seminal fluid proteins) are overrepresented among the most rapidly evolving genes
351 on every branch of the *dunni* group phylogeny (Supplementary Table 6, *p*-value < 0.05 after multiple testing
352 correction). This is consistent with rapid evolution occurring in genes involved in the reproductive conflict
353 between the sexes (Figure 4) (HAERTY *et al.* 2007). While not significant outliers, we also find that immune
354 recognition proteins, antiviral RNA and piRNA pathways are also rapidly evolving in some species,
355 consistent with arms races between the species and their parasites (Supplementary Table 6).

356 **Figure 4:** Rates of evolution across the *Drosophila dunni* phylogeny, showing non-synonymous divergence
357 versus synonymous divergence across **A.** the whole phylogeny and **B.** comparing the proportion of non-
358 synonymous to synonymous divergence between *D. nigrodunni* and *D. arawakana*. JAK-STAT, Toll and
359 seminal fluid proteins are highlighted due to their enrichments in one or the other species.



360

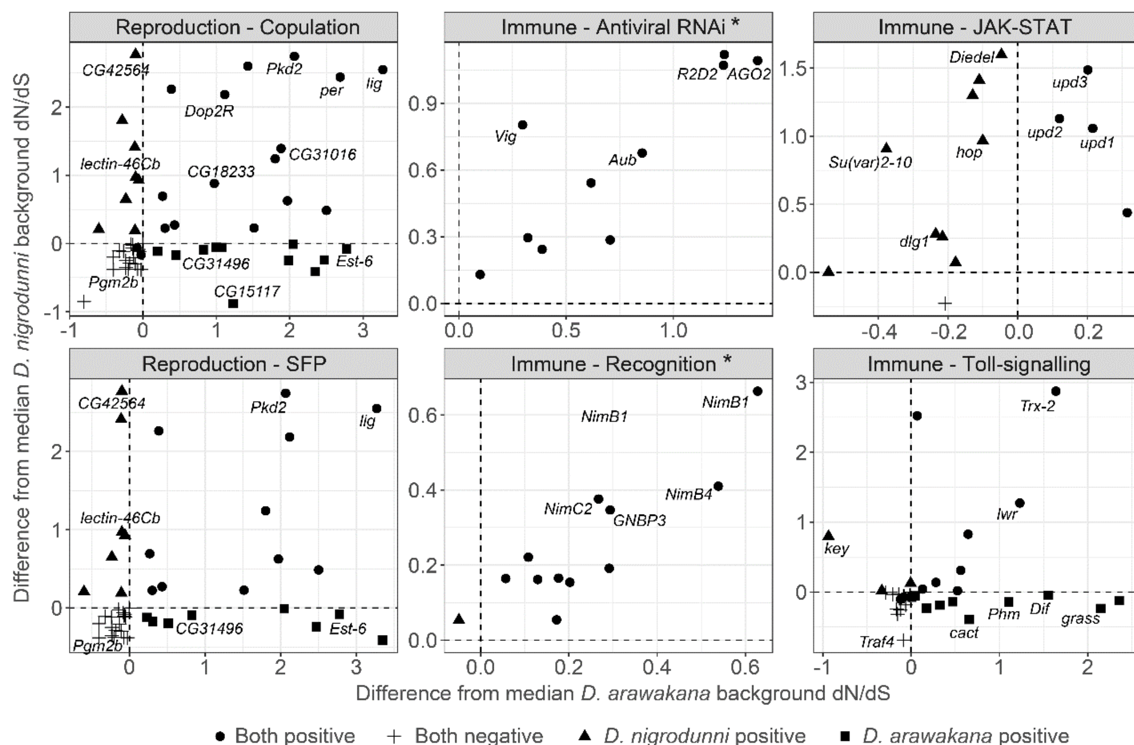
361 Rapidly evolving genes may provide clues into the selective forces acting on species since their
362 divergence. For the main species pairs of interest (e.g. *D. nigrodunni* and *D. arawakana*) we identified
363 genes in the upper 97.5th percentile for windows of dN/dS in the other species, to find genes rapidly evolving
364 in one species but not the other (Figure 2B). As expected, copulation-associated proteins were in the upper
365 97.5th percentile for both species, while genes in the Toll immune pathway are rapidly evolving in *D*
366 *arawakana* but not *D. nigrodunni¸* conversely the JAK-STAT immune pathway is rapidly evolving in *D.*
367 *nigrodunni* but not *D. arawakana* (Supplementary Table 6, Figure 4B). These results suggest each species

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

368 may differ in their primary pathogen, resulting in context dependent immune evolution, as seen elsewhere
369 in the *Drosophila* subgenus (OBBARD *et al.* 2009; HILL *et al.* 2019).
370 We sought to confirm the rapid evolution of reproductive pathways and immune pathways after
371 controlling for the background rate of evolution. We found the difference between dN/dS for each immune
372 and reproductive gene and genes at neighboring loci on the chromosome (within 100kbp), of similar levels
373 of divergence (+- 0.01 dS). We find significantly elevated rates of evolution of antiviral genes, insemination
374 genes and seminal fluid proteins across the entire phylogeny (Figure 5, one-sided T-test mu = 0, *p*-value =
375 0.0434). We also find a significant correlation between differences in *D. arawakana* and *D. nigrodunni* for
376 antiviral genes (Pearson's correlation = 0.795, t-value = 2.163, *p*-value = 0.0288), immune recognition
377 genes (Pearson's correlation = 0.877, t-value = 5.791, *p*-value = 0.000175) and piRNA genes (Pearson's
378 correlation = 0.659, t-value = 3.506, *p*-value = 0.00292). The highest average rate of evolution occurred
379 seminal fluid proteins on the *D. nigrodunni* and *D. arawakana* branches (Figure 5, one-sided T-test, mu =
380 0, *p*-value < 0.05). Consistent with previous results we find elevated rates of evolution of the Toll signaling
381 pathway in *D. arawakana*, and JAK-STAT in *D. nigrodunni*. Interestingly, when comparing the specific
382 genes rapidly evolving between *D. nigrodunni* and *D. arawakana*, the specific insemination and seminal
383 fluid genes are mostly evolving at different rates between species (Figure 5), while the other rapidly
384 evolving genes are consistent between species (Figure 4B). Consistent with this, we find no correlation
385 between measures between *D. arawakana* and *D. nigrodunni* in copulation (Pearson's correlation = 0.187,
386 t-value = 1.417, *p*-value = 0.162), seminal fluid proteins (Pearson's correlation = 0.0341, t-value = 0.224,
387 *p*-value = 0.823), JAK-STAT (Pearson's correlation = 0.185, t-value = 0.625, *p*-value = 0.545) or Toll-
388 signaling proteins (Pearson's correlation = 0.450, t-value = 1.334, *p*-value = 0.224). This could suggest a
389 difference in importance of insemination proteins between the species and could even suggest a functional
390 divergence (HAERTY *et al.* 2007).

391 **Figure 5:** Difference of dN/dS between focal genes in specific functional categories and their nearby
392 background genes. We find different insemination proteins and seminal fluid proteins are rapidly evolving
393 between *D. nigrodunni* and *D. arawakana*. A selection of genes in each category are labelled by name in
394 each plot. Plots are labelled with a * if we find a positive correlation between the two axes (*p*-value < 0.05).

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.



395

396 Using orthology to *D. innubila,* we also identified duplications relative to these two species in each
397 *dunni* group genome, and specific to each species. Consistent with the estimates in rates of evolution, we
398 find enrichments of duplications in cell motility and copulation across the entire phylogeny (Supplementary
399 Figure 6, Supplementary Table 7). We also find enrichments of duplications in Toll signaling genes in *D.*
400 *arawakana* (*p*-value = 0.000569, enrichment = 5.44). Overall this suggests that the pathways showing
401 elevated levels of nucleotide divergence (namely Toll and Copulation genes) also have more copy number
402 variation between species than expected.

403 **Discussion**

404 *Drosophila* species have served as prominent models in genetics research, including in understanding the
405 divergence between populations and the evolution of species. This is facilitated by the extensive genetic
406 tools available in the species group to identify the genetic basis of reproductive isolation, both prezygotic
407 and postzygotic. Many islands contain endemic species of *Drosophila* with differing levels of isolation. For
408 example, the island endemics in the *Drosophila simulans* complex (CABOT *et al.* 1994; KLIMAN *et al.* 2000;
409 MATUTE AND AYROLES 2014), with *D. mauritiana, D. simulans* and *D. sechellia* have served as a rich
410 system for understanding reproductive isolation (CABOT *et al.* 1994; KLIMAN *et al.* 2000). Like the
411 *Drosophila simulans* complex, the *Drosophila dunni* species subgroup has radiated across a chain of islands
412 (HEED 1962), though with easier to define species relationships than is seen in the *simulans* subcomplex
413 (CABOT *et al.* 1994; KLIMAN *et al.* 2000; MATUTE *et al.* 2014). Due to the recent radiation of this group,

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

414 many species pairs in the *dunni* subgroup produce offspring (STALKER AND STREISINGER 1953; HEED
415 1962), some of which are fertile, and so provide a potentially useful model system for dissecting the genetics
416 of reproductive isolation.

417 Here, we assessed the extent of hybrid incompatibilities between species of the *dunni* subgroup,
418 focusing on post-mating-prezygotic incompatibilities. We then sequenced and assembled the species
419 genomes to identify highly divergent and rapidly evolving genes. Between *D. nigrodunni* and *D.*
420 *arawakana,* we find elevated divergence of several immune system pathways, as well as divergence in
421 genes involved in copulation. This divergence fits with the hybrid male inviability between these two
422 species, as well as the reduced survival of females following insemination by a heterospecific male.
423 Consistent with the divergence in the seminal fluid proteins, we find evidence of an insemination reaction-
424 like swelling of the reproductive tract (KNOWLES AND MARKOW 2001), and a decrease in hybrid mating
425 compared to within species.

426 Strangely, in this study most of the striking differences appear when comparing *D. nigrodunni* and
427 *D. arawakana* (Figures 1-5). This pair is slightly less diverged than other pairings within the group
428 (Supplementary Figure 1) and are allopatrically separated (HEED 1962; WILDER AND HOLLOCHER 2003),
429 allowing for the neutral accumulation of substitutions with a reduced chance of introgression or
430 reinforcement (COYNE AND ORR 1989; COYNE AND ORR 2004). Due to this reduced divergence and
431 reduced incidence of incompatibilities (ORR 1995; WELCH 2004), we may have caught this species pair at
432 the opportune time where these hybrid incompatible effects are visible, while other species pairs are too far
433 diverged (Figure 1).

434 The functional annotation of the more diverged genes may also provide us with clues as to how
435 these species are diverging. As we find premating- behavior proteins are divergent between *D. arawakana*
436 and *D. nigrodunni*, this may result in a divergence in premating behavior, resulting in the reduced rate of
437 hybrid matings scored (Figure 3). We also see no difference in the proportion of hybrid matings after 24
438 hours and 48 hours, suggesting that in these cases, if a female has rejected all males, she may not change
439 her mind later (COYNE AND ORR 2004; GOURBIÈRE AND MALLET 2010; TURISSINI *et al.* 2017).
440 Hybridization between island-endemic flies separated by ~500 kilometers of ocean may be unlikely
441 (COYNE *et al.* 1982), but selection against hybridization between our focal species and other *dunni* group
442 species may have led to the evolution of reinforcement against heterospecific mating (GOURBIÈRE AND
443 MALLET 2010; TURISSINI *et al.* 2017). We also find seminal fluid and copulation proteins are rapidly
444 diverging between species (Figure 2) and find an increased incidence of swollen and deformed reproductive
445 tracts, consistent with an insemination reaction-like effect and a toxic incompatibility between the SFPs
446 and their environment (Figures 2 and 3) (MARKOW AND ANKNEY 1988; KNOWLES AND MARKOW 2001).
447 In fact, studies in other species have also identified post-mating-prezygotic incompatibilities to be a driver

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

448 of isolation between species, even in cases with gene flow (GAVRILETS AND WAXMAN 2002; GAVRILETS
449 2003; LARSON *et al.* 2012; LARSON *et al.* 2013; AHMED-BRAIMAH 2016; TURISSINI *et al.* 2017). A recent
450 study identified the upregulation of the JAK-STAT pathway (a stress response pathway) in *Drosophila*
451 females following heterospecific mating, likely due to the negative effects of the accessory gland proteins
452 (AHMED-BRAIMAH *et al.* 2020). The rapid evolution of JAK-STAT proteins in *D. nigrodunni* could also be
453 due to this species requiring a well-adapted stress response pathway, given its negative reaction to
454 heterospecific matings (Figures 1-3).

455 Several of the functional gene categories identified in this study as highly divergent between
456 species are also promising regions for future study, particularly when focusing on immune evolution. Our
457 findings are consistent with other studies that find immune proteins are more rapidly evolving than
458 background genes (SACKTON *et al.* 2007; OBBARD *et al.* 2009; SHULTZ AND SACKTON 2019), consistent
459 with an arms-race between the host and its pathogens. However, in the species studied here, we find several
460 cases of species-specific rapid evolution of an immune pathway, such as the rapid evolution of JAK-STAT
461 in *D. nigrodunni* (Figures 4 and 5). As immune pathways are constantly evolving in response to their
462 pathogens, this could be explained by differences in immune pathogens in this species group (SACKTON *et*
463 *al.* 2007; UNCKLESS *et al.* 2016; HILL *et al.* 2019). Hypothetically, the lack of any substantive natural Gram-
464 Negative bacterial pathogens in *D. dunni* would result in a lack of divergence in the IMD pathway, the
465 immune pathway associated with the resisting Gram-Negative bacteria. While a lack of fungal or Gram-
466 Positive bacterial pathogens in *D. nigrodunni* could result in the lack of evolution of the Toll pathway, but
467 rampant evolution in *D. arawakana* (Figures 4 and 5).

468 The repetitive content also appears to be diverging rapidly across this species complex
469 (Supplementary Figure 5). This is commonly seen between species, given the elevated mutation
470 rate/transposition of selfish factors compared to the rest of the genome (KOFLER *et al.* 2012; KOFLER *et al.*
471 2015; ADRION *et al.* 2019), and has been implicated in the formation of hybrid incompatibilities for several
472 species (SATYAKI *et al.* 2014). Consistent with this we find several TE families unique to specific species
473 in the *dunni* complex. However, we did not find a significant excess of dysgenic ovaries in hybrid females
474 compared to normal females (Fisher's exact text p-value > 0.05 for all cases). Several cases of hybrid
475 incompatibilities caused by differences in TE content results in sterility caused by maternally inherited
476 factors over paternally inherited (as is usually seen). This may be due to the absence of maternally loaded
477 silencing RNAs against specific TEs (BINGHAM *et al.* 1982; ARAVIN *et al.* 2007; BRENNECKE *et al.* 2008).
478 If this were the case, we would expect the hybrid sterility to be in the opposite direction to what we observe,
479 with sterile females (Figure 1, Supplementary Figure 5) (KIDWELL *et al.* 1977), and so do not expect the
480 hybrid incompatibilities seen here to be caused by repetitive content. However, this is a simplistic view of
481 the effects of transposon activity on hybrid fertility, given the complex hybrid dysgenesis cases seen in *D.*

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

482 *virilis* (PETROV et al. 1995; EVGEN'EV et al. 1997; ERWIN et al. 2015), and even the complex cases of
483 tolerance to dysgenesis seen in the supposedly simple case in *D. melanogaster* (KELLEHER et al. 2018), so
484 may require further study to fully understand if TEs play a role in the divergence of the *dunni* complex.

485 Overall, our findings suggest that the rapid divergence of reproductive genes has led to
486 incompatibilities between species in the *dunni* group, including inviable male offspring and the
487 insemination reaction associated with reduced female survival. We also find multiple areas for further
488 investigation in the *D. dunni* group, either in immune evolution of continuing to investigate the speciation
489 in this species group, suggesting promise in the future of research for this group.

720 **Supplementary Information**

721 **Supplementary Table 1:** Table of next-generation sequencing information used in this survey with number
722 of reads per sample and accession numbers per sample.

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

723 **Supplementary Table 2:** Average number of offspring from each set of crosses, either heterospecific or
724 conspecific crosses after 1 week of mating and 1 week of egg laying. Table also shows the sex ratio of
725 offspring and if offspring of each sex are fertile.

726 **Supplementary Table 3:** Table showing average synonymous divergence between each species pair.

727 **Supplementary Table 4:** Table summarizing genome assembly statistics of each species sequenced and
728 assembled chromosomes, including number of scaffolds for each chromosome, the length of each
729 chromosome, and coding and intronic proportions.

730 **Supplementary Table 5:** Summary statistics of genomes sequenced assembled and annotated in this
731 study, including number of genes, the number of these that have orthologs in *D. virilis* and *D.*
732 *melanogaster*, as well as statistics regarding size of these genes.

733 **Supplementary Table 6:** Gene categories enriched for high dN/dS (either the upper 95th percentile or
734 dN/dS > 1) across the entire phylogeny and on each species branch, also the upper outliers for *D.*
735 *nigrodunni* and *D. arawakana* relative to the other species.

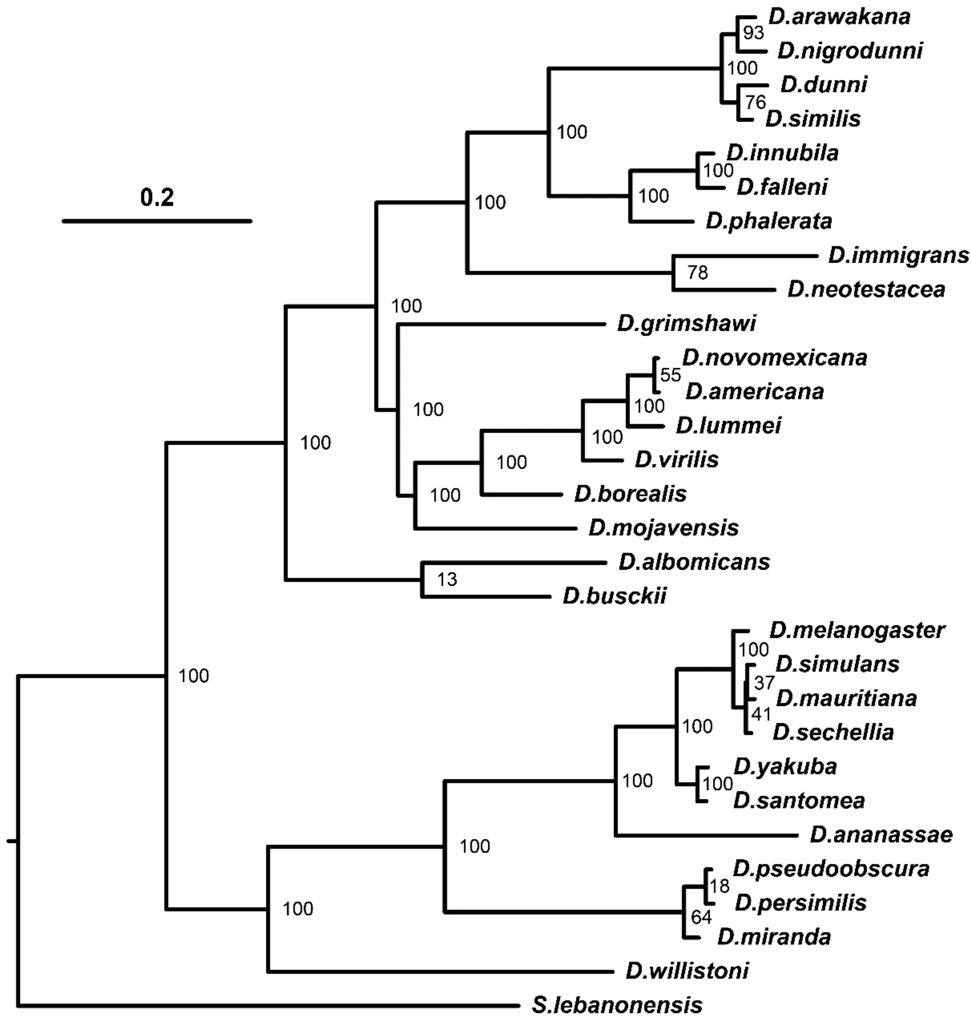
736 **Supplementary Table 7:** Gene categories enriched for duplications on each branch of the *D. dunni*
737 species phylogeny, relative to unduplicated genes.

738 **Supplementary Table 8:** dN/dS statistics calculated using codeML for the entire *dunni* phylogeny and
739 on each branch.

740

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

741 **Supplementary Figure 1:** Phylogeny of the *dunni* group relative to other *Drosophila* species. Phylogeny
742 was calculated using PhyML (GUINDON *et al.* 2010), finding the consensus of 100 genes, with bootstrap
743 values (the number that match out of 100) shown at nodes.



744

bioRxiv preprint doi: https://doi.org/10.1101/2020.05.20.106724. this version posted May 22, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

745 **Supplementary Figure 2:** Survival probability of females for each species used in each cross, compared
746 to virgin female survival. Crosses following curing of the strain with Tetracycline-Hydrochloride. Females
747 are separated by species, and grouped as virgins, conspecific crossed (crossed to own species),
748 heterospecific crossed (crossed to a different species). In the case of heterospecific crosses, *D. arawakana*
749 is only crossed to *D. nigrodunni* and *D. dunni* is only crossed to *D. similis*.

754 **Supplementary Figure 4:** Orthologous regions between the *D. nigrodunni* genome, *D. dunni* genome and
755 *D. innubila* genome. Syntenic regions on the same chromosome (shown as Muller elements, A-F) are
756 labelled with grey ribbons, while syntenic regions between difference chromosomes are labelled in red.

758 **Supplementary Figure 5:** Proportion of each genome made up of repetitive content (colored by
759 classification of repetitive content) For simplicity, the satellite category contains Satellites,
760 microsatellites, simple repeats tandem repeats and low complexity regions. **A.** Comparison of TE
761 annotation between two tools, DNApipeTE and Repeatmodeler. **B.** Comparison of TE content across
762 species and if that content is shared between species or is unique to one species.
